Incubation of Japanese quail eggs at different temperatures: hatchability, hatch weight, hatch time and embryonic mortality

Temperature is the most important factor affecting embryonic development, hatchability and post hatch performance. Optimum incubation temperature is normally defined as that required to achieve maximum hatchability. This work was carried out to verify the effects of different incubation temperatures on hatchability, hatch weight, hatch time and embryonic mortality of Japanese quail eggs. A total of 800 eggs were divided in eight experimental groups that were incubated at different temperatures (34, 35, 36, 37, 38, 39, 40 and 41ºC). The other incubation conditions were identical for all groups, 60±5% of relative humidity and egg turning every two hours until transference to the hatchers at 15 days of incubation. The results showed that fertile hatchability was higher for eggs incubated at 37 and 38ºC, 76.6 and 80.7%, respectively. Eggs incubated at 34ºC did not hatch and the ones incubated at 35 and 41ºC showed very poor hatchability. The other temperatures had hatch rates from 50.3 to 57.7%. There were higher hatch weights in eggs incubated at high temperatures (38-41° C) compared to the ones incubated at the lower ones (35-37° C). There was an enormous difference in the hatching time according to the incubation temperature. The difference of time between the groups of eggs that hatched earlier (40° C) compared to the ones the hatcher later (35° C) was 156.3 hours or 6.5 days. Embryos seemed to be resistant to at high temperatures until 40° C at the early period of incubation, however the same was not observed at the later stages of incubation when high temperatures (39-41° C) increased embryonic mortality.

Incubação de ovos de codornas japonesas em diferentes temperaturas: eclodibilidade, tempo de nascimento, peso ao nascer e mortalidade embrionária

A temperatura é o fator mais importante para o desenvolvimento embrionário, a eclodibilidade e o desempenho pós-nascimento de aves. A temperatura ideal é normalmente aquela que permite máxima eclodibilidade. Este trabalho verificou os efeitos de diferentes temperaturas de incubação sobre a eclodibilidade, perda de peso dos ovos, peso ao nascer, tempo de nascimento e mortalidade embrionária de ovos de codornas japonesas. Foram utilizados 800 ovos, divididos em oito grupos experimentais e incubados em diferentes temperaturas (34, 35, 36, 37, 38, 39, 40 e 41ºC). As demais condições de incubação foram idênticas para todos os grupos, 60±5% de umidade relativa e viragem a cada 2 horas até a transferência para a nascedoura no 15º dia de incubação. A eclodibilidade dos ovos férteis foi maior para os ovos incubados a 37 e 38ºC; 76,6 e 80,7%, respectivamente. Os ovos incubados a 34ºC não eclodiram e os incubados a 35 e 41ºC apresentaram um índice muito baixo de eclodibilidade. As outras temperaturas proporcionaram eclodibilidade entre 50,3 e 57,7%. Os pesos ao nascer foram elevados nos grupos incubados em temperaturas altas (38-41ºC) quando comparados aos grupos incubados em temperaturas baixas (35-37ºC). Observou-se diferença no tempo de nascimento de acordo com a temperatura de incubação. A diferença de tempo entre o grupo de ovos que eclodiram mais cedo (40ºC) e os ovos que eclodiram por último (35ºC) foi de 156,3 horas ou 6,5 dias. Os embriões apresentaram-se resistentes a altas temperaturas até 40ºC durante o período inicial da incubação, contudo o mesmo não foi observado nos estágios finais da incubação, quando altas temperaturas (39-41ºC) aumentaram a mortalidade embrionária.

INTRODUCTION

The performance of artificial incubation in poultry species, including Japanese quails, can be affected by a series of factors, such as egg turning (Moraes et al., 2008), relative humidity (Romao et al., 2009), egg storage (Romao et al., 2008, 2010; Moraes et al., 2009), and others, however temperature is considered to be the most important factor affecting embryonic development (Romanoff, 1972), hatchability (Deeming and Ferguson, 1991) and post hatch performance (Wilson, 1991). Embryonic development and incubation period depends on the age of the embryo, duration of exposure as well as humidity, type of incubator and temperature (Wilson, 1991). During artificial incubation, the embryo temperature is dependent on incubator temperature, embryonic metabolic rate, and thermal conductance of the egg and surrounding air (French, 1997). Optimum incubation temperature is normally defined as that required to achieve maximum hatchability (French, 1997). However, Decuypere and Michels (1992) have argued that the quality of the hatchlings should also be considered.

The incubation process on domestic chicken can be performed under temperatures higher or lower than the one considered optimum for the specie (37.5°C). However, changes in incubational temperature may alter the standard embryonic development with detrimental effects for hatchability (Alda, 1994). The major effects of incubation at temperatures outside the optimal range are increases in embryonic mortality, deformities and failure to hatch (Romanoff, 1960; Lundy, 1969).

There are several studies that observed the effect of temperature on length of incubation (Michels et al., 1974; French 1994, Suarez et al., 1996), on the rate of embryo growth (Decuypere et al., 1979; Dias and Muller, 1998), and on hatchability (Wilson, 1991; Lourens et al., 2005). However, there are few studies about these effects on Japanese quail incubation performance.

This work was carried out to evaluate the effect of different incubation temperatures on hatchability, hatch weight, hatching time and embryo mortality of Japanese quail eggs.

MATERIAL AND METHODS

A total of 150 Japanese quails (Coturnix japonica) were used for egg collections. The birds were reared in experimental cages in the Laboratório de Estudos Ornitológicos- Universidade Estadual do Ceará. They were lodged at a ratio of two females and one male in each cage. Birds were 22 week old and averaged 90% of egg laying production. All quails were supplied with balanced feed, water ad libitum and exposed to 17 hours/day of light.

The eggs were selected for incubation verifying egg shape, extreme sizes and eggshell integrity by candling. They were divided into eight experimental groups according to incubation temperature. The eggs were incubated at 34°C (n=100), 35°C (n=100), 36°C (n=100), 37°C (n=100), 38°C (n=100), 39°C (n=100), 40°C (n=100) and 41°C (n=100) from day 0 to hatching. Each group of eggs was incubated in a separated incubator, according to its experimental incubation temperature. Incubation process was done by automatic incubators with relative humidity of 60±5% and egg turning every 2 hours. At the 15th day of incubation (360h) egg turning was stopped and the eggs were transferred to the hatchers which maintained the same temperature and relative humidity until hatch.

All eggs were identified, individually, and weighed, by a precision balance (0.001g), on the first day of incubation. After transfer at the hatchers, the eggs...
were monitored to verify their hatching time every six hours. All quail chicks were weighed individually after hatching.

Eggs that failed to hatch were opened for macroscopically observation, thus they were classified according to time of embryonic mortality. They were staged as infertile, early death embryos (1 up to 4 days), intermediate (5 up to 15 days) and late death embryos (16 up to 18 days), according to Pedroso et al. (2006).

Each experimental group (n=100) consisted of five replicates of 20 eggs. All data were analyzed using the Statistix software 8.0 (2003). The results were submitted the test of Shapiro-Wilk to verify normality and to Bartlett’s test to verify homogeneity of variances. Hatchability, chick/egg weight and hatch time means were submitted to Analysis of Variance through general linear model and the means were compared with the test of Tukey. Embryonic mortality means were compared through Kruskal-Wallis’ test. Statements of significance were based on P<0.05.

RESULTS

Table 1 shows the total hatchability which consisted of hatch rate of all eggs incubated and the fertile hatchability which was obtained from incubated eggs excluding the infertile eggs.

![Table 1 - Total and fertile hatchability of Japanese quail eggs incubated in different temperatures](image)

The eggs incubated at 37°C and 38°C had the highest hatchabilities. They were followed by the eggs incubated at 36°C, 39°C and 40°C that presented fertile hatch rates between 50.3% and 57.3%. The lowest hatch rates were found for the eggs incubated at 35°C and 41°C. It was verified that extremely high or low temperatures were very harmful for egg hatchability.

![Figure 1 - Chick/egg weight ratio (%) of Japanese quail eggs incubated in different temperatures.](image)

![Figure 2 - Hatching time of Japanese quail eggs incubated at different temperatures.](image)

The chick/egg weight of Japanese quail chicks varied between 66.7% to 75.5%, showing that incubation temperature promoted a variation up to 13% of Japanese quail hatch weight. The highest proportional weights at hatch were observed for eggs incubated at the 38°C, 39°C 40°C and 41°C. Their means of hatch
The table 2 shows the classification of eggs that failed to hatch after incubation in different temperatures. The eggs were considered infertile, early embryo death, intermediate embryo death, late embryo death or pipped egg with dead embryo. The rate of infertile eggs ranged from 8% to 12% of total eggs. This classification of unhatched egg is not dependant of incubation temperature, this way there was no statistical difference among groups. The early embryonic death was more critical for eggs incubated in extreme temperatures such as 34°C and 41°C. The intermediate embryo death was higher in eggs incubated at 34°C and lower levels were found in the central temperatures (36 to 40°C). The late embryonic death was lower in eggs incubated at 37 and 38°C, while the other temperatures presented higher levels. Only eggs incubated at 34°C had no pipped eggs. In general, the eggs incubated at 37 and 38°C had lower levels of unhatched eggs while the other presented higher levels reaching 100% for eggs incubated at 34°C.

**DISCUSSION**

**Hatchability**

The highest hatch rates were found for eggs incubated at 37°C and 38°C which is in accordance to the optimal temperature...
to the development of the chicken embryos that occurs within the narrow temperature range of 37 to 38 °C (Romanoff, 1960). Pedroso et al. (2006) found similar fertile hatchability for Japanese quail eggs incubated at 36.5°C and 37.5°C, that was 76.57% and 76.55%, respectively. The eggs incubated at 34°C were not able to hatch, however these eggs presented quail embryos that developed up to final stages. The temperature of 35°C was detrimental for embryo survival promoting a poor hatchability (4.36%). It has been reported that hypothermic incubation (35°C) promotes a series of physiological dysfunctions in chicken embryos (Black and Burggren, 2004а,b). The incubation at 36°C presented much better hatch rate compared to 35°C, however it was considerably lower than 37 and 38°C. The temperatures above 38°C were also harmful to quail embryos decreasing the hatch rates. Incubation temperatures above the optimal have been reported to negatively impact hatchability, feed conversion, BW, and general post-hatch chick and poult performance (Gladys et al., 2000). However higher and lower than optimal incubation temperatures may not be considered completely detrimental to quail incubation since it can be used in an intermittent way throughout the incubation. Callebaut (1990) studied artificial incubation of Japanese quail eggs trying to mimic the natural incubation conditions with daily 8 hours interruptions (low temperatures) and he found that it was possible to lengthen the embryonic period by one-third without apparent harm and with potential improvement in hatchability.

**Hatching Time**

The incubation time can be influenced by many factors like temperature (Suarez et al., 1996; Wilson, 1991), egg weight (Burton and Tullet, 1985), age of breeder (Smith and Bohren, 1975) and also preincubation storage (Bohren, 1978). Incubation temperatures above the optimal temperature have been reported to accelerate growth rates of avian embryos (Romanoff, 1960; Christensen et al., 1999). The incubation temperature highly influenced the hatching time of Japanese quail eggs. The lowest temperature that allowed embryo hatching was 35°C. Compared to 38°C this temperature increased almost 5 days in the hatching time. Chicken eggs incubated in the same temperatures had a lower difference between the hatching times, which was 4 days (Tazawa et al., 1988). Pedroso et al. (2006) found similar hatching times for Japanese quail eggs; eggs incubated at 36.5°C and 37.5°C hatched after 442.5 and 413.6 hours, respectively. The change of incubation temperature for small periods can also influence the hatching time as reported by Leandro et al. (2000) who

chick/egg weight ratio from eggs incubated in a lower and in a higher temperature. However they found a higher difference which was 51.5% and 64.4% for 36.5°C and 37.5°C, respectively. Hammond et al. (2007) verified that higher incubation temperatures of 38.5°C compared to 37.5°C increases not only the chick hatch weight but it also increases leg bones, more muscle fibers and nuclei in the gastrocnemius, more *in ovo* embryo motility during incubation and a reduction in adipose tissue. However much higher temperatures can be potentially detrimental to incubation of quail eggs, since Leksrisompong (2005) observed that chicken eggs incubated in temperatures from 39.5 to 40.6°C showed body weight, and weights of the heart, gizzard, proventriculus, and small intestines frequently reduced.

**Hatch Weight**

The incubation temperature promoted a higher hatch weight in eggs incubated at high temperatures (38-41°C) compared to the ones incubated at the lower ones (35-37°C). In a general way the higher temperatures tended to increase the hatch weight. This was also observed by Pedroso et al. (2006), who found an increase

verified the effects of small period (5 hours) of heat (40°C) or cold (32°C) stress in chicken eggs incubated at 37.8°C and observed an increase of hatching time of around 10 and 8 hours, respectively.

**Embryonic Mortality**

Embryo mortality pattern of Japanese quail eggs was similar to the one observed in chickens, in which there are two phases of increased embryonic mortality during incubation: the first phase occurs during the first week of incubation and the second phase during the last week (Jassim et al., 1996). In general, all embryo mortality classifications tended to be lower for eggs incubated in the central temperatures (37°C and 38°C). Embryos seemed to be resistant to embryo death in high temperatures of incubation until 40°C at the early period of incubation, however the same was not observed at the later stages of incubation when high incubation temperatures (39-41°C) promoted high levels of embryo mortality (late death and pipped eggs). These results are in accordance to Ono et al. (1994) that verified that chicken embryos are more susceptible to high temperatures in the end of incubation. Both extremes of high and low incubation temperatures may reduce hatchability due to the lack of a complete capacity to thermoregulate its own temperature since the embryos are poikilotherm until hatch.

**CONCLUSIONS**

The most suitable machine setting incubation temperatures for Japanese quail eggs were 37 and 38°C, constantly. Higher and lower temperatures resulted in low hatch rates. In general, high incubation temperatures (38, 39, 40 and 41°C) increased hatch weight and decreased hatching time, while lower temperatures (34, 35, 36 and 37°C) resulted in the opposite.
